What this page is

Your tumor was surgically removed with no visible cancer left behind, and you have finished the heavy part of treatment. The question now is maintenance: a gentler, longer-running therapy meant to keep the cancer from coming back, or to push back the day it does. Libby looked at the maintenance options that fit your tumor's specific features and your stated preferences, then ranked them and wrote down the tradeoffs in plain terms.

A word on the numbers below. When a trial reports how long people went before their cancer grew again, that is "progression-free survival." It is not the same as living longer overall, and where the two differ we say so. Median means the halfway point: half the people did better than that number, half did worse. None of these are promises about you. They are what happened, on average, to groups of patients in studies.

What we know about your cancer

You have high-grade serous ovarian cancer, stage IIIc, which is an advanced stage but one where maintenance treatment is standard and worthwhile. Surgery removed all the cancer the surgeon could see (an "R0" result). Your blood tumor marker (CA-125) has come down into the normal range, and a sensitive blood test that looks for traces of tumor DNA now reads "not detected." Both are good signs.

The tumor gene test is back, and it answers the question that was holding up the maintenance decision. You do not carry a BRCA mutation, in your tumor or inherited. That matters because the very best-studied PARP-inhibitor maintenance is reserved for BRCA-mutated cancers, and that door is closed for you. But the test also shows your tumor is "genomically unstable," meaning its chromosomes are scrambled and broken in a way that, in trials, predicts PARP-inhibitor pills can still help even without a BRCA mutation. So PARP inhibitors are still on the table, just a different group of them.

Two other findings rule some things out rather than in. The tumor is "microsatellite stable" with a low number of mutations, which together mean the immunotherapy drugs that work for mutation-heavy cancers would not be expected to help here. Your tumor is also estrogen-receptor positive, which opens the door to a gentle hormone-blocking pill as a low-key option.

What you told us matters most

You leaned toward chasing effectiveness, while staying mindful of side effects given your age. Two side effects you specifically did not want: more nerve damage in your hands or feet, and severe drops in your blood counts, the kind that bring infections or bleeding. You preferred a pill, or something with a light infusion schedule, over heavy IV regimens. And because of your history of blood clots and a filter placed in a vein, you asked for caution with any drug that raises clotting or bleeding risk. You were also open to trials.

One lab test worth getting first

There is a single lab test still worth ordering, and it does one specific job. It is a validated "genomic instability score" run on tumor tissue you already have stored, with results back in about two to three weeks. It does not involve a new biopsy and has no side effects.

Here is what it decides. Most of the options below are available to you no matter what this test shows. But one option, the strongest on paper, is a combination of a PARP pill (olaparib) added to the bevacizumab you are already on. That combination is only approved for tumors that score above a set threshold on this exact test. Your tumor looks unstable on the gene report, but that report does not measure the score this approval requires. If the score comes back high enough, that combination opens up. If it comes back below the line, it is off the table, and the other options below are unaffected.

The options

Option 1 — Rucaparib (a PARP-inhibitor pill)

Rucaparib is an oral pill you would take twice a day for up to two years. In a large, well-run trial where neither patients nor doctors knew who got the drug, people on rucaparib went a median of about 20 months before their cancer grew again, versus about 9 months on placebo, so roughly double. The benefit held up in patients without a BRCA mutation, which is why it fits your tumor without needing any further test.

The main cost is your blood counts. About 29 in every 100 people had a severe drop in red blood cells (anemia), and a smaller share had drops in infection-fighting white cells. This lands directly on one of the side effects you said you wanted to avoid, so it is not something to wave away. About 12 in 100 stopped the drug because of side effects. There can also be a temporary rise in liver blood tests, which here would start from a normal baseline. The honest ceiling: this is a "delays recurrence" benefit. The trial has not shown that it makes people live longer overall.

This is the lead option to discuss first. It is oral, which matches what you wanted, and the evidence is strong and has been confirmed in more than one study. The catch is the blood-count risk, which would mean regular blood tests, a plan worked out with a blood specialist before starting, and dose adjustments along the way.

Option 2 — Niraparib (a PARP-inhibitor pill)

This option carries caveats. Niraparib is the close cousin of rucaparib: another once-daily PARP pill, with its own large, blinded trial. There, people went a median of about 14 months before the cancer grew again, versus about 8 months on placebo. It enrolled patients regardless of BRCA status, so it fits your tumor directly. There is also a small lab-dish signal suggesting niraparib may concentrate inside tumors like yours better than some other PARP drugs, though that is early, indirect evidence rather than proof.

The tradeoff to weigh sits squarely on your blood counts, and it is why this carries caveats. Severe drops in platelets (the cells that clot your blood) happened in about 29 of every 100 people, and severe anemia in about 31 of 100. Your white-cell count is already on the low side, which leaves less reserve. This is exactly the side effect you flagged. None of that means the drug is wrong for your tumor; the open question is whether it can be delivered safely at your starting counts. The usual answer is to set the starting dose by your weight and platelet count and to have a written plan for managing low counts. With that plan documented, the concern shifts from "should we" to "how." Like rucaparib, the proven benefit is delaying recurrence, not lengthening overall survival, and the bigger effect seen in BRCA-style tumors does not apply to you.

Option 3 — Bevacizumab (continue what you are on)

Bevacizumab is an IV drug, given every three weeks, that you are already taking. It starves the tumor's blood

supply. In its anchor trial, people on it went a median of about 14 months before progression versus about 10 months without, a real but smaller gap than the PARP options. Be clear-eyed about the ceiling: across the whole study population it did not help people live longer overall, only delayed progression.

What makes it attractive is what it does not do. It does not cause the nerve damage or the severe blood-count drops you wanted to avoid. Its main side effects are high blood pressure (in about 23 of 100, manageable with standard medicine) and, rarely, a tear in the bowel wall (under 3 in 100). The one real tension with your history is that this class can raise clotting and bleeding risk, which matters given your prior clots and vein filter. That is handled by monitoring blood pressure and watching for bleeding rather than by stopping, and you are already tolerating it. The open question is whether to keep bevacizumab on its own or add a PARP pill once the lab score is back.

Option 4 — GEN-1 (the trial drug you are already on)

GEN-1 is the investigational immune-gene therapy you received as part of a trial, delivered into the abdominal cavity rather than as a pill or a standard IV. It works by stirring up the immune system right where the cancer lives, which sidesteps the reason ordinary immunotherapy would not help your tumor. In its trial, people went a median of about 15 months before progression versus about 12 months, and there was an early signal that it might help people live longer, though that survival number is not yet mature and the data have not been fully published.

The honest weaknesses: the effectiveness numbers come from a company summary and a conference abstract, not a peer-reviewed paper with a full safety table, so the side-effect picture is incomplete. The delivery route is into the belly, not the pill you preferred. And access outside the trial is not guaranteed. The case for staying on it is continuity: this is part of the regimen that got you to a clean surgery, and you said you were open to trials.

Option 5 — Letrozole (a hormone-blocking pill)

Letrozole is a once-daily pill that lowers estrogen, which can slow estrogen-driven tumors like yours. It is the gentlest option here: no nerve damage, no blood-count drops, none of the side effects you flagged. Its main downsides are joint aches and gradual bone thinning with long use. It suits your preference for a simple oral drug.

The reason it sits low on the list is the evidence. It rests on a single look-back study of past patients rather than a proper trial, so the numbers (about 60% of patients free of recurrence at two years versus about 39%) should be read as a hint, not a result you can bank on. Your tumor is estrogen-positive but progesterone-negative, and that combination usually means a more modest hormone response than the estrogen reading alone would suggest. Think of letrozole as a low-burden fallback or add-on, especially if you would rather not take a drug that hits your blood counts.

Option 6 — Olaparib plus bevacizumab (the combination, only if the lab score qualifies)

This option is only available if the genomic-instability test comes back high enough. If it comes back below the threshold, this combination is off the table, and Libby's options on this page are scoped to your tumor's specific features, so there are no other ranked choices that depend on that result. Standard later-line care for ovarian cancer still exists, but it is outside this page's scope and is a conversation for your oncologist.

This option also carries caveats. On paper it is the strongest of the lot: in the qualifying group, people went a median of about 37 months before progression versus about 18 months, roughly double again, and you are already taking the bevacizumab half. But two real concerns hold it back. First, that big number comes from a slice

of the trial population, not the whole trial; across everyone the gap was smaller (about 22 versus 17 months). Second, the side effects stack. Combining the two drugs pushed severe side effects up toward 57 of every 100 people, with high blood pressure in about 19 of 100 (which presses on your clotting history) and anemia in about 17 of 100 (the blood-count drop you flagged). So this one trips two of your concerns at once. It only becomes worth serious discussion if the lab score qualifies you and a clotting-and-blood-pressure plan is in place; if so, it could move from last choice toward first.

Questions to ask your oncologist

- The genomic-instability score is the one test that decides whether the olaparib-plus-bevacizumab combination is open to me. Can we order it now, and what is our plan for each result, high or low?
- If we start a PARP pill (rucaparib or niraparib), how often will you check my blood counts, and at what point would you lower the dose or pause? Can a blood specialist help set my starting dose given my counts are already on the low side?
- Between rucaparib and niraparib, is there a reason to prefer one for my tumor, and do they differ in how hard they hit blood counts?
- I am already on bevacizumab. Is the plan to continue it alone, or to add a PARP pill once the lab score is back? What would tip that decision?
- Given my history of blood clots and my vein filter, how will we watch for clotting or bleeding on bevacizumab, and would adding olaparib make that risk meaningfully worse?
- If the genomic-instability score comes back below the cutoff, what changes, and what would you recommend then?
- Letrozole is the gentlest option but the weakest evidence. Is it worth considering on its own, or only as an add-on or later fallback?
- For GEN-1, what does staying on the trial look like from here, and what happens to my access if the trial ends?
